Abstract

Synthetic aperture radar (SAR) autofocus techniques that optimize sharpness metrics can produce excellent restorations in comparison with conventional autofocus approaches. To help formalize the understanding of metric-based SAR autofocus methods, and to gain more insight into their performance, we present a theoretical analysis of these techniques using simple image models. Specifically, we consider the intensity-squared metric, and a dominant point-targets image model, and derive expressions for the resulting objective function. We examine the conditions under which the perfectly-focused image models correspond to stationary points of the objective function. A key finding is that the sparsity assumption of the SAR image alone is not enough to guarantee a stationary point; our analytical results show how metric-based methods rely on the multichannel defocusing model of SAR autofocus to enforce this stationary point property for multiple image columns. Furthermore, our analysis shows that near the perfectly-focused image, the objective function can be well approximated by a sum of 1-D functions of each phase error component. This allows fast performance through solving a sequence of 1-D optimization problems for each phase component simultaneously. Simulation results using the proposed models and actual SAR imagery confirm that the analysis extends well to realistic situations.

Index Terms

synthetic aperture radar, autofocus, sharpness optimization, sparsity condition, iterative methods.

I. INTRODUCTION

In synthetic aperture radar (SAR) imaging, inaccurate range measurements or signal propagation through media with unknown spatially-varying propagation velocity can cause demodulation timing errors in the radar receiver. The result of the demodulation errors is undesired Fourier phase shifts in the imaging data that cause the formed imagery to be improperly focused. Specifically, the effect of the errors frequently may be modeled by a one-dimensional phase error function added to the Fourier phase of each column of the imaging data [1]. SAR autofocus encompasses the class of image restoration techniques for correcting the unknown phase aberrations using the defocused data and assumptions about the underlying scene.

Many solutions to the SAR autofocus problem have been proposed [1]–[14]. A widely-utilized autofocus technique is Phase Gradient Autofocus (PGA), which employs the basic principles of inverse filtering, and augments them with an innovative iterative windowing and averaging process to estimate the phase error [1], [5]–[8]. PGA typically produces an accurate approximation of the phase error for a variety of errors. Exceptional restoration quality has been observed through the use of a class of autofocus methods that optimize image sharpness metrics [9]–[15]. In these metric-based autofocus methods, the compensating phase estimate is selected through an optimization algorithm to maximize a particular sharpness metric evaluated on the defocused image intensity. Examples of the optimization approaches used in these methods include gradient-descent techniques [9], coordinate direction searches [11], and monotonic iterative algorithms [10], [12], [16]. The use of metric-based autofocus algorithms sometimes produces superior restorations in comparison with the conventional PGA method in experiments using synthetic and actual SAR imagery [15], [17].

Much of the current understanding of metric-based autofocus techniques is based on intuition and results from processing data sets. Thus, it is of interest to obtain a clearer understanding of the performance of these autofocus methods. Such an understanding might enable the powerful restoration ability of these methods to achieve more widespread use. Sharpness metrics were first explored in 1974 by Muller and Buffington for the real-time correction of phase distortions in telescopic imaging systems [18]. Some recent work was done by Fienup et al. in justifying the use of particular metrics for SAR given prior assumptions on the underlying image model [9]. The goal of our work is to gain further insight into metric-based methods for SAR autofocus through studying a simple dominant point-targets image model. Such a model has been used to motivate existing autofocus approaches [1], [5], [9], [11]. Considering the intensity-squared metric, we derive expressions for the objective function as a function of the parameters
of the proposed models and also the unknown phase errors. Our expressions, which describe the variation of the metric along the phase-error coordinate directions, are used to determine the conditions under which the perfectly-focused SAR image models correspond to stationary points of the objective function (i.e., points of zero gradient) [19]–[21]; these are points where the optimization algorithms used in metric-based autofocus terminate.

Because the phase error is a one-dimensional function of the cross-range frequency coordinate, each range bin (i.e., column of the image) is defocused by the same blurring kernel; we denote this as the multichannel defocusing model of SAR autofocus [22], [23]. It has been observed that autofocus approaches generally require multiple columns of the defocused image to produce an accurate estimate of the phase error function; this is true of metric-based methods as well [11]. Thus, it is not the sharpness metric or image model alone that allows the image to be properly restored, but also the redundancy of the defocusing operation on each image column. Our key contribution is that we conclusively demonstrate how the assumption of the multichannel defocusing model is exploited in metric-based SAR autofocus methods. Our analysis shows that one-dimensional point-target models, such as a single column of the perfectly-focused image, generally do not correspond to stationary points of the objective function. However, accurate estimation of the phase error is possible when the objective function is evaluated for multiple image columns; the (objective function) minima from multiple columns reinforce each other, or average, to form a stationary point at the perfectly-focused phase estimate. It is through this averaging mechanism that metric-based methods implicitly use the multichannel assumption and correctly estimate the phase error.

We also demonstrate that near the perfectly-focused image, the objective function can be well approximated by a sum of 1-D functions of each phase error component. Thus, we show that, locally, the multivariate objective function is a separable function of the phase perturbations. This finding allows fast optimization using a simultaneous coordinate descent approach, where a sequence of 1-D optimization problems are solved for each phase component simultaneously, and underlies the success of efficient monotonic algorithms for metric-based SAR autofocus [10].

The organization of this paper is as follows. Section 2 presents a statement of the SAR autofocus problem. The image model and sharpness metric used in our analysis are defined, and we state the optimization problem for metric-based SAR autofocus methods. In Section 3, we derive expressions for the intensity-squared objective function using one-dimensional (single-column) image models. Section 4 extends the analysis to two-dimensional (multi-column) images. Using a stochastic image model where the parameters of the model are selected according to a particular distribution, we demonstrate that as
multiple image columns are combined to form the objective function, the gradient at the perfectly-focused phase estimate approaches zero, satisfying the stationary point condition. In Section 5, we show that the multivariate objective function is approximately a separable function of the phase perturbations locally about the perfectly-focused solution. In Section 6, we present numerical experiments using actual SAR imagery to validate the analytical results and show that the analysis extends well to realistic situations.

II. Problem Setup

A. The Autofocus Problem

Let $g \in \mathbb{C}^{M \times N}$ be the perfectly-focused SAR image. After range compression (inverse 1-D DFT in the range direction), the collected Fourier imaging data $G \in \mathbb{C}^{M \times N}$ are related to $g$ through a 1-D DFT applied to each column [24]:

$$g[m,n] = \text{DFT}^{-1}_k \left\{ G[k,n] \right\} = \frac{1}{M} \sum_{k=0}^{M-1} G[k,n] e^{j2\pi km/M}.$$  

(1)

Here, the row index $m$ ($m = 0, 1, ..., M - 1$) corresponds to the cross-range dimension, the column index $n$ ($n = 0, 1, ..., N - 1$) to the range dimension, and $\text{DFT}^{-1}_k$ denotes an inverse DFT with respect to the cross-range frequency index $k$ ($k = 0, 1, ..., M - 1$).

In practice, $G$ is corrupted by multiplicative phase errors that produce a defocused image. A mathematical model relating the defocused Fourier imaging data $\tilde{G}$ to the focused data $G$ is [1]:

$$\tilde{G}[k,n] = G[k,n] e^{j\phi_e[k]},$$  

(2)

where $\phi_e \in [-\pi, \pi]^M$ is a 1-D Fourier phase error function. Using (1) and (2), the defocused image is related to the perfectly-focused image through

$$\tilde{g}[m,n] = \text{DFT}^{-1}_k \left\{ \text{DFT}_m \left\{ g[m',n] e^{j\phi_e[k]} \right\} \right\}.$$  

(3)

Autofocus algorithms form an estimate $\hat{\phi}_e$ of the phase error function to correct the defocused imaging data, forming the restored image

$$\hat{g}[m,n] = \text{DFT}^{-1}_k \left\{ \tilde{G}[k,m] e^{-j\hat{\phi}_e[k]} \right\}.$$  

(4)

B. SAR Image Models

We utilize a dominant point-targets model for the SAR image. Such a model can be considered as a rough representation of SAR and ISAR images when there is strong return from isolated scatterers. This simple, yet analytically tractable model has been used to motivate existing autofocus approaches [1], [5],

October 26, 2006
We consider the sparse discrete signal \( g_s \in \mathbb{C}^{M \times N} \), where each column of \( g_s \), representing a fixed range coordinate \( n \) or a single range bin, contains \( P \) weighted impulses:

\[
g_s[m,n] = \sum_{p=0}^{P-1} a_p[n] e^{j\theta_p[n]} \delta[m - m_p[n]],
\]

where \( \delta[m] \) is the discrete unit impulse signal. Each impulse represents a point target with magnitude \( a_p[n] \), spatial-domain phase shift \( \theta_p[n] \), and location \( m = m_p[n] \). We assume that the number of dominant targets is much smaller than the number of resolution cells (pixels) per range bin: \( P \ll M \).

## C. Image Sharpness Metrics

Metric-based autofocus algorithms use image sharpness metrics to evaluate the degree of focus. Because of the point-like nature of the SAR image model, maximizing sharpness is found to increase the image focus. The aim of these methods is to determine the image in the search space (4) with maximum sharpness, as measured by a particular metric.

The metrics we consider are additive in the sense that the value of the metric, or cost, is a sum of contributions from each pixel individually. We define \( \varphi : \mathbb{R}^+ \rightarrow \mathbb{R} \) as a concave cost function operating on the intensity of each pixel \( I[m,n] \) defined \( |g[m,n]|^2 \). In this paper, we study the intensity-squared cost function \([9], [11], [12], [14], [18]\)

\[
\varphi(I) = -I^2.
\]

The metric \( C : \mathbb{C}^{M \times N} \rightarrow \mathbb{R} \) maps the image \( g \) to a sharpness cost:

\[
C(g) = \sum_{n=0}^{N-1} \sum_{m=0}^{M-1} \varphi(|g[m,n]|^2).
\]

Due to the concavity of \( \varphi \), sharpening the image (increasing the variance of the pixel intensities about their mean) decreases the value of the cost \( C \) \([9]\). Therefore, we wish to minimize the metric \( C \) (maximize sharpness).

## D. SAR Autofocus as an Optimization Problem

The objective function for the defocused image \( \tilde{g} \), \( f_{\tilde{g}} : [-\pi, \pi)^M \rightarrow \mathbb{R} \), is defined as

\[
f_{\tilde{g}}(\phi) = C(\tilde{g}_\phi),
\]

where \( \tilde{g}_\phi[m,n] = DFT^{-1}_k \{ \tilde{G}[k,m] e^{-j\phi[k]} \} \) is an image in the search space (4). In other words, \( f_{\tilde{g}}(\phi) \) is the metric evaluated in the space of images formed from \( \tilde{g} \) by applying a particular Fourier phase correction function \( \phi \).
Metric-based autofocus methods employ optimization algorithms, which act on $\phi$ to determine a minimizer of $f_{\bar{g}}$. However, the optimization techniques used in these methods may determine local minimizers of $f_{\tilde{g}}$ [25], [19]. Therefore, we are interested in the behavior of the objective function locally about the perfectly-focused image. We introduce the function

$$f_g(\phi) = C(g_{\phi}),$$

(9)

where $g_{\phi}[m, n] = DFT_k^{-1}\{G[k, m]e^{-j\phi[k]}\}$. The function $f_g$ is the objective function where the origin $\phi = 0$ is defined with respect to $g$ instead of $\tilde{g}$: $f_{\bar{g}}(\phi) = f_{\tilde{g}}(-\phi_e + \phi)$.

The key in our analysis is to derive expressions for $f_g(\phi e_k)$, where $e_k$ is the $k$-th element of the standard basis for $\mathbb{R}^M$ and $\phi e_k (\phi \in [-\pi, \pi])$ is the $k$-th component of $\phi$, using the model $g_s$ in (5); note that $\phi$ is a scalar and $\phi$ (in boldface) is a vector. Such expressions describe the objective function along the phase-error coordinate directions $\{e_k\}_{k=0}^{M-1}$. The expressions are used to determine the conditions under which $g_s$ corresponds to a stationary point of the objective function. Stationary points are places where the gradient-based optimization algorithms in metric-based SAR autofocus terminate; such points satisfy the first-order necessary condition for optimality [19], [21]. The stationary point condition requires zero gradient at the origin of the objective function [19]:

$$\nabla f_g(0) = 0,$$

(10)

where

$$\nabla f_g(\phi) \bigg|_{\phi=0} = \left[ \frac{\partial f_g(\phi e_0)}{\partial \phi} \bigg|_{\phi=0}, \ldots, \frac{\partial f_g(\phi e_{M-1})}{\partial \phi} \bigg|_{\phi=0} \right].$$

(11)

III. ANALYSIS OF SINGLE-COLUMN IMAGE MODELS

A. Approximate Expressions for the Objective Function

In this section, we analyze one column of the dominant point-targets model $g_s$ in (5), which represents a fixed range coordinate $n$ (i.e., a single range bin):

$$g[m] = \sum_{p=1}^{P} a_p e^{j\theta_p} \delta[m - m_p].$$

(12)

We first characterize the effect on the image of perturbing a single component $\phi e_k$ of the Fourier phase of $g$. Such a characterization is then used to derive an approximate expression for the squared image intensity as a function of $\phi e_k$, which leads directly to expressions for $f_g(\phi e_k)$.

The perturbed image $g_{\phi e_k}$ is defined as the image formed by perturbing the $k$-th component of the Fourier phase of $g$ by an amount $\phi$ (i.e., $\angle G[k] + \phi$):

$$g_{\phi e_k}[m] \overset{\text{def}}{=} DFT_k^{-1}\{DFT_{m'}\{g[m']\}e^{j\phi[k'-k]}\}.$$
This may be alternatively expressed as

$$g_{\phi e_k}[m] = g[m] + \varepsilon_{\phi e_k}[m],$$  \tag{14}$$

where

$$\varepsilon_{\phi e_k}[m] = (e^{j\phi} - 1) s_k[m],$$  \tag{15}$$
is the update to pixel $m$ due to $\phi$, and $s_k[m]$ is the subband image

$$s_k[m] = \frac{1}{M} G[k] e^{j2\pi km/M}.$$  \tag{16}$$
The $(e^{j\phi} - 1)$ term comes from subtracting out the $k$-th term in the Fourier sum where the phase has not been perturbed, and adding in a new term where the phase has been perturbed by $\phi e_k$.

We derive an approximate expression for the squared intensity of the perturbed image: $I_{\phi e_k}^2[m] = |g_{\phi e_k}[m]|^4$. Using (14),

$$I_{\phi e_k}^2[m] = |g[m] + \varepsilon_{\phi e_k}[m]|^4 = ((g[m] + \varepsilon_{\phi e_k}[m])(g^*[m] + \varepsilon_{\phi e_k}^*[m]))^2$$  \tag{17}$$
= |g[m]|^4 + 4\Re\{|g[m]|^2g^*[m]\varepsilon_{\phi e_k}[m]| + 2|g[m]|^2|\varepsilon_{\phi e_k}[m]|^2
+ 4\Re\{|\varepsilon_{\phi e_k}[m]|^2g^*[m]\varepsilon_{\phi e_k}[m]| + 4(\Re\{g^*[m]\varepsilon_{\phi e_k}[m]|\})^2 + |\varepsilon_{\phi e_k}[m]|^4,$$$$
where $\Re$ denotes the real part of the argument. We approximate (17) by retaining the first two terms; this is equivalent to the first-order Taylor series expansion of (17) about $\varepsilon_{\phi e_k}[m] = 0$:

$$I_{\phi e_k}^2[m] \approx I^2[m] + 4\Re\{I[m]g^*[m]\varepsilon_{\phi e_k}[m]|,$$$$
where $I[m] = |g[m]|^2$ and $I^2[m] = |g[m]|^4$. The benefit of using an approximation is that the expression is linear in the image update $\varepsilon_{\phi e_k}[m]$, which will result in a simplified and intuitive expression for the objective function. To justify that (18) is an accurate approximation, we show that $|\varepsilon_{\phi e_k}[m]| \ll |g[m]|$ at pixels where a target is present (i.e., $m = m_p$). Using $|(e^{j\phi} - 1)| \leq |\phi| \leq \pi$, and $|G[k]| \leq \sum_m |g[m]| \leq P\|g\|_\infty$ on (15) and (16), we have the upper bound

$$|\varepsilon_{\phi e_k}[m]| \leq \frac{P}{M} |\phi|\|g\|_\infty$$  \tag{19}$$
for all $m$ and $k$. Thus if

$$\frac{P}{M} |\phi| \ll 1,$$$$
then the approximation in (18) is accurate. Note that this is true for the sparse model (12) where $P \ll M$.

As an example, let $P = 24$, $M = 1024$, and $|\phi| = \pi$. Then $\frac{P}{M} |\phi| \approx 0.074 \ll 1$. Since $|\varepsilon_{\phi e_k}[m]|$ decreases with decreasing $\phi$, the approximation (18) becomes especially good for small phase perturbations (e.g.,
Thus, the expression for the objective function will be highly accurate locally about the perfectly-focused solution.

Using (15) and (18), the intensity-squared objective function evaluated for a single phase perturbation $\phi e_k$ is expressed as

$$f_g(\phi e_k) = - \sum_{m=0}^{M-1} I_{\phi e_k}^2[m]$$

$$\approx - \sum_{m=0}^{M-1} I^2[m] - \Re \left\{ (e^{j\phi} - 1) z_k \right\},$$

where

$$z_k = 4 \sum_{m=0}^{M-1} I[m] g^*[m] s_k[m].$$

Note that (21) can be rewritten as

$$f_g(\phi e_k) \approx c_k - |z_k| \cos(\phi + \angle z_k),$$

where $c_k = - \sum_{m=0}^{M-1} I^2[m] + \Re \{ z_k \}$ is a constant given the perfectly-focused image.

The expression (23) reveals that the behavior of $f_g(\phi e_k)$ for every $k$ is described by a cosine function with an amplitude and phase shift dependent on the complex number $z_k$, which is a function of the perfectly-focused image model. We note that expressions similar to (23) have been derived independently in [10] and [12] using different approximations and assumptions.

Using (12), we define (22) explicitly in terms of the model parameters:

$$z_k = 4 \frac{M}{P} \sum_{p=0}^{P-1} \sum_{l=0}^{P-1} a_l^3 a_p e^{j \psi_k[l,p]}$$

where

$$\psi_k[l,p] = \theta_p - \theta_l + \frac{2\pi}{M} k (m_l - m_p).$$

The contribution of the spatial-domain phases and the locations of the pair of targets at $m = m_l, m_p$ resides exclusively within the parameter $\psi_k[l,p]$.

The expression (24) shows that $z_k$ is generally not real-valued, so $\angle z_k \neq 0$ in general. For the stationary point condition of $f_g(\phi e_k)$ given in (23) to be satisfied, a necessary and sufficient condition is that $\angle z_k = 0$ for all $k$. The presence of the $\angle z_k$ phase shift causes the minima of $f_g(\phi e_k)$ to be displaced from the origin, so that the perfectly-focused image does not correspond to a stationary point.
Fig. 1. An approximate expression for the objective function using the intensity-squared cost: (a) perfectly-focused range bin model, and (b) plots of $f_g(\phi e_{18})$ versus $\phi \in [-\pi, \pi)$ for the model in (a), where the solid plot shows the exact numerically evaluated metric, and the dashed plot uses the approximate expression in (23).

B. Validation of the Approximate Expression

Figure 1(a) shows the magnitude of a three-target realization of the image model (i.e., $P = 3$) with $M = 128$. The plot in Figure 1(b) shows the behavior of the objective function along the coordinate direction $e_{18}$ (selected as a representative example) on the interval $[-\pi, \pi)$ for the model in Figure 1(a). The exact numerically evaluated metric is displayed as a solid curve, and the approximate expression in (23) is displayed as a dashed curve. The approximate expression is observed to be in excellent agreement with the exact expression, particularly for small $\phi$. Similar agreement is found using other directions $e_k$ and other realizations of the model $g$.

In this example, the objective function in Figure 1(b) does not have a minimum at the origin (since the minimum of $f_g(\phi e_{18})$ is not at $\phi = 0$), and applying the optimization to the perfectly-focused image would produce an erroneous restoration. In general, metric-based methods cannot restore a single column of the SAR image. However, we will show that the image model in (5) with multiple image columns can be properly focused through these techniques. In the next section, we demonstrate that the combination of the objective functions arising from each column individually causes the origin of the objective function for the multi-column image to approach a stationary point.
IV. ANALYSIS OF MULTI-COLUMN IMAGE MODELS

A. Asymptotic Analysis

In the previous section, we determined expressions for the objective function considering only a single image column. Since the metrics we consider are additive, the objective function evaluated for a multi-column image can be expressed as the sum of the objective functions evaluated for each image column individually:

\[ f_g(\phi_e_k) = \sum_{n=0}^{N-1} f_{g[n]}(\phi_e_k), \]  

(26)

where \( g[n] \) denotes the \( n \)-th column of \( g \). Our goal is to show that when a large number of columns of the point-targets model are incorporated, the origin of the objective function approaches a stationary point. To quantitatively demonstrate this, we employ a stochastic image model for \( g \) in analogy with (5):

\[ g[m, n] = \sum_{p=0}^{P-1} A_p[n] e^{j \Theta_p[n]} \delta[m - m_p[n]], \]  

(27)

where \( A_p[n] \) and \( \Theta_p[n] \) are random variables characterizing the target magnitudes and spatial-domain phases, respectively. The following statistical assumptions are used in the analysis:

- The magnitudes \( A_p[n] \) are independent and identically distributed (i.i.d.), with a distribution on \( \mathbb{R}^+ \) having a finite variance.
- The spatial-domain phases \( \Theta_p[n] \) are independent and uniformly distributed between \(-\pi\) and \(\pi\).
- The random variables \( A_p[n] \) and \( \Theta_p[n] \) are independent of each other.

The target locations \( m_p[n] \) may be arbitrary, given that no two targets are assigned the same location: \( m_p[n] \neq m_q[n] \) for all \( p, q \). The random phase assumption is accurate for many scenarios where the surface roughness is on the scale of the radar wavelength [1], [26], [27]. In fact, the assumption has been shown to be important for SAR image reconstruction; similar to holographic imaging, random phase permits formation of high-resolution images from bandlimited, frequency-offset Fourier data [26].

Using the expression (21) in (26) yields

\[ f_g(\phi_e_k) \approx -\sum_{n=0}^{N-1} \sum_{m=0}^{M-1} I^2[m, n] - \Re \left\{ (e^{j\phi} - 1) \sum_{n=0}^{N-1} Z_k[n] \right\}, \]  

(28)

\[ = C_k - \left| \sum_{n=0}^{N-1} Z_k[n] \right| \cos \left( \phi + \angle \sum_{n=0}^{N-1} Z_k[n] \right) \]

where \( Z_k[n] \) is the coefficient \( z_k \) in (25) evaluated for range coordinate \( n \) using the model (27):

\[ Z_k[n] = \frac{4}{M} \sum_{p=0}^{P-1} \sum_{l=0}^{P-1} A_l[n] A_p[n] e^{j \Psi_k[l, p, n]}, \]  

(29)
\[ \Psi_k[l, p, n] = \Theta_p[n] - \Theta_l[n] + \frac{2\pi}{M} k(m_l[n] - m_p[n]), \]  
\[ (30) \]

and \( C_k = -\sum_{m,n} I^2[m, n] + \Re\{\sum_n Z_k[n]\} \). Note that since \( A_p[n] \) and \( \Theta_p[n] \) are i.i.d. in \( n \), \( Z_k[n] \) is an i.i.d. sequence in \( n \) for every \( k \).

Define
\[ \Omega_k^{[N]} = \angle \sum_{n=0}^{N-1} Z_k[n] \]  
\[ (31) \]
to be the phase shift associated with the \( k \)-th coordinate direction. The Strong Law of Large Numbers will be used to show that, as \( N \) becomes large, the sum over \( Z_k[n] \) converges to its expected value (scaled by \( N \)). We then will show that the expected value is real-valued, so that \( \lim_{N \to \infty} \Omega_k^{[N]} = 0 \) for all \( k \), demonstrating that \( \phi = 0 \) is a stationary point of \( f_g \). For fixed \( k \), the Strong Law implies that with probability one [28]:
\[ \frac{1}{N} \sum_{n=0}^{N-1} Z_k[n] \to E_{A,\Theta}[Z_k] \text{ as } N \to \infty, \]
\[ (32) \]
where \( E_{A,\Theta} \) is the expected value with respect to \( A \) and \( \Theta \). Due to the uniform distribution on the spatial-domain phases, from (30) we see that \( e^{j\Psi_k[l,p,n]} = 1 \) if \( l = p \) and otherwise is uniformly distributed on the unit circle, so that
\[ E_{\phi}[e^{j\Psi_k[l,p,n]}] = \begin{cases} 1 & \text{for } l = p \\ 0 & \text{otherwise}. \end{cases} \]
\[ (33) \]
As a result, only terms in (29) where \( l = p \) contribute to the expectation:
\[ \mu_Z \overset{\text{def}}{=} E_{A,\Theta}[Z_k] = \frac{4}{M} PE_A[A^4]. \]
\[ (34) \]
Therefore, for large \( N \) we have
\[ \sum_{n=0}^{N-1} Z_k[n] \approx N \mu_Z, \]
\[ (35) \]
which due to (34) is positive and real-valued.

Using (35), the expression (28) for large \( N \) becomes
\[ f_g(\phi e_k) \approx C - N \mu_Z \cos(\phi), \]
\[ (36) \]
where \( C = -\sum_{m,n} I^2[m, n] - N \mu_Z \). Thus, we see that the stationary point condition is satisfied (i.e., \( \left. \frac{\partial f_g(\phi e_k)}{\partial \phi} \right|_{\phi=0} = 0 \) for all \( k \)), and the metric is nondecreasing along each coordinate direction.
B. Quantitative Analysis for a Finite Number of Columns

Expressing the phase shift (31) in terms of the real and imaginary parts of $Z_k[n]$:  
$$\Omega_k^{[N]} = \tan^{-1} \left[ \frac{\sum_{n=0}^{N-1} \Im \{Z_k[n]\}}{\sum_{n=0}^{N-1} \Re \{Z_k[n]\}} \right],$$  
(37)

where $\Im$ specifies the imaginary part of the argument. We approximate (37) using two observations. First,  
$$\sum_{n=0}^{N-1} \Re \{Z_k[n]\} \gg \sum_{n=0}^{N-1} \Im \{Z_k[n]\},$$  
which is based on (35) being purely real; this implies  
$$\Omega_k^{[N]} \approx \frac{\sum_{n=0}^{N-1} \Im \{Z_k[n]\}}{\sum_{n=0}^{N-1} \Re \{Z_k[n]\}}.$$  
(38)

Furthermore, it can be shown that the expected value of the denominator in (38) is much greater than its variance, so we make the approximation that only the variation in the numerator is significant, and approximate the denominator using its mean $\sum_{n=0}^{N-1} \Re \{Z_k[n]\} \approx N\mu_Z$:  
$$\Omega_k^{[N]} \approx \frac{\sum_{n=0}^{N-1} \Im \{Z_k[n]\}}{N\mu_Z}.$$  
(39)

To determine how quickly the phase shifts tend to zero, we examine the variance as a function of $N$. Using (39), It can be shown that  
$$\sigma_\Omega^2 [N] \equiv \text{Var}[\Omega_k^{[N]}] \approx \left( \frac{\lambda P - 1}{2} \right) \frac{1}{N},$$  
(40)

where  
(41)

Since (39) is a sum of i.i.d. random variables with finite variance, by the central limit theorem $\Omega_k^{[N]}$ approaches a normal distribution with mean zero and variance $\sigma_\Omega^2 [N]$ [29]. The key is noting that as the number of columns increases, the variance of the phase shifts decreases as $1/N$. Thus, there is fast convergence to a stationary point with a relatively small number of columns.

C. Validation of Analytical Results

We consider the stochastic image model in (27) with $M = 64$ and $P = 9$, where the target magnitudes $A_p$ are uniformly distributed on the interval $(0, 1]$ and the target locations are selected at random without replacement from the set of indices $m_p \in \{0, 1, \ldots, M-1\}$. One column of this model is shown in Figure 2(a). Figures 2(b)-(f) show an experiment demonstrating the reinforcement of metric minima as an increased number of columns are included in the stochastic model. Plots of the objective function along each coordinate direction $f_g(\phi e_k)$, $k = 0, 1, \ldots, M - 1$, (where, for comparison, the plots have been scaled to unity and the constant offset has been removed) are shown superimposed in Figure 2(b).
Fig. 2. Demonstration of the reinforcement of metric minima as an increased number of columns are included in the stochastic model. (a) One column of the stochastic model ($P = 9$, $M = 64$). (b)-(f): Normalized plots of the objective function along each coordinate direction $f_y(\phi e_k)$, $k = 0, 1, \ldots, M - 1$ (shown superimposed), where (b) $N = 1$, (c) $N = 3$, (d) $N = 10$, (e) $N = 64$, and (f) $N = 256$. 
for a single column of the stochastic model \((N = 1)\). The metric minima are observed to be distributed with a large variance about \(\phi = 0\). Figure 2(c) shows plots of the objective function for \(N = 3\); here, the metric minima are distributed more closely about the origin. Further plots for \(N = 10\), \(N = 64\), and \(N = 256\) are shown in Figures 2(d), (e), and (f), respectively. These figures reveal that as more image columns are introduced, the contributions of the phase shifts \(\angle Z_k[n]\) associated with each column average out, producing a stationary point at the origin.

To examine how the deviations of the metric minima from the origin decrease with an increasing number of columns, we examine the squared \(\ell_2\)-norm of the phase shifts as a function of \(N\): 

\[
\|\Omega^{[N]}\|_2^2
\]

where \(\Omega^{[N]}\) is a vector of the phase shifts from every coordinate direction \(k = 0, 1, \ldots, M - 1\). Figure 3 shows a plot (in log scale) of \(\|\Omega^{[N]}\|_2^2\) for the stochastic model considered in the experiment of Figures 2(a)-(f); this plot is displayed using cross markers. It can be shown that \(\|\Omega^{[N]}\|_2^2 \rightarrow M \sigma_{\Omega}^2[N]\) as \(N\) increases. A plot of \(M \sigma_{\Omega}^2[N] \sim \frac{1}{N}\) is shown in the dashed curve of Figure 3 for comparison. The plots reveal that the deviations from \(\phi = 0\) decrease sharply in the regime of small \(N\). We can infer from this that the averaging effect takes place for a relatively small number of range bins containing dominant point targets; this provides justification for why metric-based methods work well for many practical SAR images.
In summary so far, we have demonstrated that, in general, a single column of the dominant point-targets model does not correspond to a stationary point. However, when the metric is evaluated on a large number of image columns, the metric minima along each \( e_k \) due to the phase shifts \( \angle Z_k[n] \) reinforce each other to form a minimum at \( \phi = 0 \). This averaging mechanism produces a stationary point at the origin, allowing the perfectly-focused image to be properly restored. This observation is the key to understanding why metric-based approaches are successful.

V. SEPARABLE APPROXIMATION FOR THE MULTIVARIATE OBJECTIVE FUNCTION

We observe that locally about the origin, the objective function is approximately a separable function of the phase perturbations. That is, within a radius of the origin (e.g., \( \| \phi \|_2 < V, V \in \mathbb{R} \)), the objective function is essentially a sum of terms that depend upon each phase component \( \phi e_k \) individually. To help formalize this finding, we derive an approximate expression for the multivariate objective function \( f_\phi(\phi) \) that is separable in \( \phi e_k \), and we show that this approximation becomes more accurate as \( \| \phi \|_2 \) decreases. This approximation provides a local characterization of the second-order properties of the objective function.

Similar to our derivation of (18), we approximate the perturbed intensity as a function of the vector of phase perturbations \( \phi \) using a first-order Taylor approximation. Analogous to (14), we write the phase-perturbed image as

\[
g_\phi[m, n] = g[m, n] + \varepsilon_\phi[m, n],
\]

where the image update can be expressed using (15) and (16) as

\[
\varepsilon_\phi[m, n] = \sum_{k=0}^{M-1} \varepsilon_{\phi_k e_k}[m, n] = \frac{1}{M} \sum_{k=0}^{M-1} (e^{j\phi_k} - 1)G[k, n]e^{j2\pi km/M},
\]

(43)

\( \phi_k \) is the \( k \)-th component of \( \phi \), and \( \varepsilon_{\phi_k e_k}[m, n] \) is defined in (15) (for fixed \( n \)). Using (42), and taking steps similar to those leading to (18) yields the approximation

\[
I^2_\phi[m, n] \approx I^2[m, n] + 4 \sum_{k=0}^{M-1} \mathbb{R}\{I[m, n]g^*[m, n]\varepsilon_{\phi_k e_k}[m, n] \}
\]

(44)

The approximation in (44) is accurate when \( |\varepsilon_\phi[m, n]| \) is small compared to \( g[m, n] \). Analogous to (19), \( |\varepsilon_\phi[m, n]| \) can be bounded from above as follows. Let \( g \) be the model described by (5). Employing steps similar to those used to derive (19), from (43) we have \( |\varepsilon_\phi[m, n]| \leq \frac{1}{M} \sum_{k=1}^{M-1} |\phi_k||G[k, n]| \leq \frac{1}{M}\|\phi\|_2\|G^{[n]}\|_2 \), where the last inequality is a result of Cauchy-Schwarz and the superscript \([n]\) denotes...
the $n$-th column. Using $\|G^{[n]}\|_2 = \sqrt{M}\|g^{[n]}\|_2 \leq \sqrt{MP}\|g\|_\infty$ we obtain

$$|\varepsilon_{\phi}[m, n]| \leq \sqrt{\frac{P}{M}}\|\phi\|_2\|g\|_\infty,$$

(45)

for all $m$ and $n$. Thus if

$$\sqrt{\frac{P}{M}}\|\phi\|_2 \ll 1,$$

(46)

then the approximation (44) is accurate. Note that this is true for sparse images ($P \ll M$) and small phase perturbations.

Using the approximation (44), we have

$$f_g(\phi) = -\sum_{n=0}^{N-1} \sum_{m=0}^{M-1} I^2_{\phi}[m, n]$$

$$\approx -\sum_{n=0}^{N-1} \sum_{m=0}^{M-1} I^2[m, n] - \sum_{k=0}^{M-1} \Re\left\{e^{j\phi_k} - 1\right\}\sum_{n=0}^{N-1} z_k[n]$$

$$= \sum_{k=0}^{M-1} f_g(\phi_k e_k) + \gamma,$$

where $z_k[n]$ is defined in (24) for (fixed $n$) and $\gamma = (M - 1) \sum_{n=0}^{N-1} \sum_{m=0}^{M-1} I^2[m, n]$.

A consequence of (47) is that when the phase errors are small enough, we can optimize the multivariate objective function $f_g(\phi)$ by optimizing each phase component in $\phi$ independently. This observation underlies the success of efficient monotonic iterative optimization algorithms for metric-based SAR autofocus [10], [12], where the phase components are optimized simultaneously and independently at each iteration.

VI. Experimental Results

To demonstrate how our analysis extends to actual SAR imagery, we performed numerical simulations using actual SAR images. We first consider the perfectly-focused 600 by 600 pixel SAR image in Figure 4(a), which is formed from a given defocused image by applying an $I^2$-minimization autofocus routine [10]. Figure 4(b) shows normalized plots of the objective function using the image in (a) for each coordinate direction. As predicted by theory, the plots of the objective function for the perfectly-focused image are described by cosine functions, with minima at $\phi = 0$ (note that since all of the plots lie on top of each other, they resemble a single plot). To show that a single column of the image does not correspond to a stationary point, we evaluate plots of the objective function for column 491 (selected as a representative example), which are displayed in Figure 4(c). The objective function minima for the single column exhibit large variation about the origin. Figure 4(b) reveals that the effect of these minima...
Fig. 4. Experiment with an actual SAR image. (a) Intensity of 600 by 600 pixel perfectly-focused SAR image (displayed in dB), (b) normalized plots of the objective function along each coordinate direction ($k = 0, 1, \ldots, 600$) for the image in (a), (c) normalized plots of the objective function for column 491 (for clarity, a subset of coordinate directions $k = 3, 11, 19, \ldots, 595$ is shown), (d) defocused image where a small phase error has been applied (independent phase components uniformly distributed between $-\frac{\pi}{3}$ and $\frac{\pi}{3}$) to the image in (a), (e) applied phase error $\phi_e[k]$ (star markers) and phase estimate formed by performing simultaneous 1-D searches along each coordinate direction (circle markers) for $k = 3, 11, 19, \ldots, 595$, and (f) image restored by applying the phase estimate in (e).
are averaged out when the contributions of all the columns are taken into account, as demonstrated in our analysis.

We have demonstrated that locally about the origin, the objective function can be approximated as a separable function of the phase perturbations. To show this using actual data, we apply a small random phase error, with independent components uniformly distributed between $-\frac{\pi}{3}$ and $\frac{\pi}{3}$, to the perfectly-focused image in Figure 4(a). The resulting defocused image is displayed in Figure 4(d). Figure 4(e) shows a plot of the phase shifts $\Omega_k$ for the defocused image (displayed in circle markers), determined by numerically performing 1-D searches along each coordinate direction, superimposed on a plot of the applied phase errors $\phi_e[k]$ (displayed in star makers) for $k = 3, 11, 19, \ldots, 595$. We see that these plots are in agreement, demonstrating that the effect of applying small phase perturbations to the perfectly-focused image is to shift the objective function minima by an amount equal to the phase errors. Thus, in the local regime, the phase error can be determined by performing $M$ simultaneous one-dimensional searches along each coordinate direction (i.e., simultaneous coordinate descent). Figure 4(f) shows the restored image formed in this manner.

The image in Figure 4(a) consists of point-like features (e.g., corner reflections) against a low-return background, and thus the model in (5) is a good approximation to this actual image. To determine how the analysis extends to actual SAR images not well-described by the dominant point-targets model, we consider the perfectly-focused terrain image of size 2027 by 2335 in Figure 5(a). As in the previous experiment, the perfectly-focused image is formed from a defocused image by applying $I^2$-minimization autofocus. Figure 5(b) shows normalized plots of the objective function using the image in (a) for the subset of coordinate directions $k = 95, 191, 287, \ldots, 2015$. As in the experiment of Figure 4, the metric minima for each coordinate direction are located at $\phi = 0$. Figure 5(c) shows plots of the objective function for a single column (column 680) for the same subset of coordinate directions. As expected, the figure reveals that the stationary point condition is not satisfied for the single image column.

From the analysis in (45), the separable approximation (47) is expected to hold well when the phase perturbations are small and the SAR image is sparse with a small number point targets per range bin. To determine how well the separable approximation holds for the image in Figure 5(a), we apply a small random phase error with independent components uniformly distributed between $-\frac{\pi}{3}$ and $\frac{\pi}{3}$. The resulting defocused image is shown in Figure 5(d). As in the experiment using the previous image, we applied a single iteration of simultaneous coordinate descent (i.e., $M$ independent 1-D searches) to the defocused image to determine an estimate of the phase error. The phase estimate is displayed in diamond markers in Figure 5(e), plotted with the actual phase error in star markers for $k = 31, 63, \ldots, 2015$. 

October 26, 2006
We observe that the phase estimate is not as accurate as the estimate produced in the experiment in Figure 4(e). This is expected, since the image in Figure 5(a) is not sparse like the previous image, and the separable approximation should hold less well. The plot denoted by circle markers in Figure 5(e) shows the result of applying three iterations of simultaneous coordinate descent; here, the phase error is recovered with a high degree of accuracy. We note that although the sparsity assumption holds weakly for the image in Figure 5(a), a rough estimate of the phase error is produced after a single iteration. However, when the applied phase errors are outside of the range \((-\frac{\pi}{3}, \frac{\pi}{3})\), we have observed through experiments that the phase estimate obtained through a single iteration is not correct. This suggests that within a neighborhood of the local optimum, simultaneous coordinate descent can converge very quickly to the true phase estimate using a small number of iterations, even when the actual SAR image is poorly approximated by the ideal model (5). The simultaneous coordinate descent can be performed efficiently in an iterative fashion using the framework in [10].

VII. CONCLUSION

We have presented analytical results providing new insight into metric-based methods for the restoration of SAR images. Considering the intensity-squared metric, and a dominant point-targets image model, we have derived a simple approximation for the resulting objective function. We demonstrated, in general, a single-column image model does not correspond to a stationary point. Thus, we saw that it is not the sharpness metric alone that makes these approaches successful, but the reinforcement of metric minima that takes effect with many image columns; it is here that the multichannel defocusing model of SAR autofocus is exploited implicitly. The necessity of the implicit multichannel assumption suggests that a means for exploiting the multichannel condition explicitly is needed. We are exploring this (i.e., see [22], [23]), where a linear algebraic formulation to the SAR autofocus problem, similar to those used in the past to study multichannel deconvolution problems, has been found to have great potential.

We have demonstrated that the multivariate objective function has a special structure near the perfectly-focused image: it is approximately a separable function of the phase perturbations. As a consequence, when the phase errors are small, the metric minima are displaced from the origin by an amount equal to the phase errors. This allows the phase error to be estimated by performing \(M\) 1-D searches along each coordinate direction simultaneously. Our analysis provides a formal justification for observations and assumptions in recent work [10], [12].
